Does Africa Need a Rotten Kin Theorem?  
Experimental Evidence from Village Economies

Pamela Jakiela and Owen Ozier

November 6, 2012

Abstract

This paper measures the economic impacts of social pressures to share income with kin and neighbors in rural Kenyan villages. We conduct a lab experiment in which we randomly vary the observability of investment returns to test whether subjects reduce their income in order to keep it hidden. We find that women adopt an investment strategy that conceals the size of their initial endowment in the experiment, though that strategy reduces their expected earnings. This effect is largest among women with relatives attending the experiment. Parameter estimates suggest that women anticipate that observable income will be “taxed” at a rate above four percent; this effective tax rate nearly doubles when kin can observe income directly. At the village level, we find a robust association between willingness to forgo expected return to keep income hidden in the laboratory experiment, and worse economic outcomes outside the laboratory. Though this paper provides experimental evidence from a single African country — Kenya — observational studies suggest that similar kin pressures may be prevalent in many parts of the developing world.

1 Introduction

Risk is a pervasive aspect of the lives of individuals in many developing economies, and informal risk-pooling arrangements which help households cope with shocks can have substantial welfare impacts when credit and insurance markets are incomplete. A substantial body of evidence documents the existence of mutual insurance arrangements throughout the world (cf. Townsend 1994, Coate and Ravallion 1993, Fafchamps and Lund 2003). Much of the literature focuses on mutual insurance arrangements which are efficient given constraints, characterizing the conditions under which self-interested households will enter risk-pooling schemes voluntarily \textit{ex ante} and the participation constraints which keep households from defecting \textit{ex post}.

However, the expectation of future transfers is only one of many reasons households offer assistance to those worse off: altruism, guilt, and social pressure to share income may also play a role (Geertz 1963, Scott 1976, Foster and Rosenzweig 2001, Alger and Weibull 2010). In fact, several recent studies suggest that individuals living in poor communities often feel obligated to make transfers to relatives and neighbors, and that successful families who do not make sufficient transfers to others can face harsh social sanctions (Platteau 2000, Barr and Stein 2008, Di Falco and Bulte 2011).

For example, Baland, Guirkinger, and Mali (2011) provide evidence of this type of behavior in Cameroon, where members of credit cooperatives take out loans to signal that they are liquidity constrained — even when they also hold substantial savings — in order to avoid sharing accumulated wealth with relatives. Such social pressure to share is not confined to Sub-Saharan Africa, or even the developing world: Geertz (1963) describes a similar phenomenon in post-independence Indonesia, while Stack (1974) documents the existence of analogous kin obligations in poor, urban communities in the United States.

In this paper, we report the results of an experiment designed to measure social pressure to share income with relatives and neighbors. We use a controlled laboratory environment to explore behaviors which are difficult to document using survey data: the willingness to forgo profitable investment opportunities to keep income secret. Our experimental design yields simple comparative static predictions, and also provides the identification necessary for structural estimation of the underlying “kin tax” parameter in the presence of heterogeneous risk preferences.

We conduct economic experiments in 26 rural communities in western Kenya. Within the experiment, subjects receive an endowment which they divide between a risk-free savings account and a risky but profitable investment. The size of the endowment varies across subjects, and the distribution of endowment sizes is common knowledge. While the amount

1See Ligon, Thomas, and Worrall (2002), Albarran and Attanasio (2003), and Kinnan (2011) for examples. Foster and Rosenzweig (2001), which explores the impact of altruism on the set of self-enforcing insurance arrangements, is an important exception.

2See Hoff and Sen (2006), Comola and Fafchamps (2010), and Dupas and Robinson (forthcoming–b) for other examples.
saved is always private information, we randomly vary whether the amount invested in the risky security can be observed by other subjects, creating an incentive for those receiving the large endowment to invest no more than the small endowment, thereby keeping their endowment size hidden. We also offer a subset of subjects the option of paying to keep their investment returns secret, allowing us to directly measure the willingness-to-pay to hide income.

In light of evidence that women and men have different risk preferences (cf. Croson and Gneezy 2009) and that women in poor communities may have more trouble accumulating savings (cf. Dupas and Robinson forthcoming–a), we stratify our experiment by gender, and report results for men and women separately. We find that women are willing to reduce their expected income to avoid making investment returns observable. Women receiving the large endowment, who may wish to hide this fact from their relatives and neighbors, are 25.4 percent (9.6 percentage points) more likely to invest an amount no larger than the small endowment when returns are observable; this is equivalent to a 5.4 percentage point decline in investment level. We find no similar tendency to hide income among men. The effect we observe among women appears to be driven primarily by the behavior of women whose payoffs are most directly visible to their kin network: those with relatives attending the experiment. Estimates suggest that these women invest 22.1 percent less when investment income is observable than when it is hidden; they are roughly 40 percentage points more likely to invest no more than the amount of the small endowment, suggesting that their strategy is designed to keep the size of their endowment hidden. Consistent with a simple model of decisions in the experiment when risk preferences are heterogeneous and subjects face pressure to share income, we find that women receiving the large endowment are more likely to invest exactly the amount of the small endowment when investment returns are observable, and that this tendency is also more pronounced among women with relatives present. Impacts are unlikely to be driven by in-laws providing information to husbands: there is no direct impact of having one’s husband present, and choice patterns are similar in the sub-sample of unmarried women.

Among subjects given the opportunity to pay a randomly-assigned price to keep income hidden, 30 percent of those able to afford the cost of hiding income choose to do so. These subjects pay an average of 15 percent of their gross payout from the experiment. Though women are no more likely than men to pay to avoid the public announcement, their willingness to do so is strongly related to the amount of observable income they receive; this is not true for men. At the village level, women’s tendency to hide income within the experiment is negatively associated with durable asset accumulation by households, skilled

---

3Dupas and Robinson (forthcoming–a) find evidence that female daily wage earners in western Kenya are more savings constrained than men in similar occupations. In a similar vein, De Mel, McKenzie, and Woodruff (2008), De Mel, McKenzie, and Woodruff (2009), and Falchamps, McKenzie, Quinn, and Woodruff (2011) find lower returns to capital for microenterprises operated by women than for those operated by men.
and formal sector employment, and the probability of using fertilizer on crops, suggesting
that social pressure to share may hinder growth and development.

After presenting our reduced form results, we estimate the magnitude of the “kin tax”
parameter via maximum simulated likelihood in a mixed logit framework. This is important
because the size of the treatment effect of observability depends on both the level of social
pressure and the distribution of individual risk preferences; decisions in our (control) private
information treatments suggest substantial heterogeneity in risk aversion across subjects.

After controlling for unobserved heterogeneity in risk preferences, we find a statistically
significant tax for women, averaging four percent in general. For women whose kin attend
the experimental session, consistent with the reduced form pattern, the tax appears to be
twice as large. Simulations suggest that this level of social pressure may lead to a dramatic
reduction in the likelihood of starting a business.

The main aim of this paper is to document the importance of social pressure in in-
terhousehold transfer relationships within kin networks in poor communities. We make
several contributions to the existing literature. First, we introduce a novel lab experiment
designed to measure social pressure to share income in field settings. The experiment is
simple to understand, but provides subjects with a rich menu of investment options and
multiple mechanisms for hiding income. Our design allows us to effectively rule out sev-
eral alternative explanations: behavior is not consistent with models of attention aversion
or a desire to avoid social sanctions against risk-taking, and the lack of a direct effect of
having one’s spouse present suggests that kin networks are not just passing information
on to husbands. Second, treatment assignments within the experiment were randomized
within villages, allowing us to explore the association between community outcomes and
income hiding in the lab. Third, we link decisions in the experiment to a model of individ-
ual investment choices when risk preferences are heterogeneous, and estimate this model
via maximum simulated likelihood. This allows us to recover an estimate of the kin tax
parameter, and to simulate the magnitude of its impact on microentrepreneurship.

The rest of this paper is organized as follows: Section 2 describes our experimental
design and procedures; Section 3 presents a simple theoretical framework for interpreting
our results; Section 4 presents our main reduced-form empirical results; Section 5 presents
our structural framework and estimates; and Section 6 concludes.

See Hey and Orme (1994); Choi, Fisman, Gale, and Kariv (2007); Andersen, Harrison, Lau, and Rutström
(2008); Choi, Kariv, Müller, and Silverman (2011), and Von Gaudecker, van Soest, and Wengström (2011) for
further experimental evidence on risk preference heterogeneity.
2 Experimental Design and Procedures

2.1 Structure of the Experiment

The experiment was designed to introduce exogenous variation in the observability of investment returns. Within the experiment, each participant was given an initial endowment, either 80 or 180 Kenyan shillings. Each subject divided her endowment between a zero-risk, zero-interest savings account and an investment which was risky but profitable in expectation. The subject received five times the amount that she chose to invest in the risky prospect with probability one half, and lost the amount invested otherwise. A coin was flipped to determine whether each risky investment was successful. Thus, the main decision subjects faced was how much of their endowment to invest in the risky security and how much to allocate to the secure, zero-profit alternative.

Within the experiment, players were randomly assigned to one of six treatments. First, players were allocated either the smaller endowment of 80 shillings or the larger endowment of 180 shillings. Endowment sizes were always private information — experimenters never identified which subjects received the large endowment. However, the distribution of endowments was common knowledge, so all subjects were aware that half the participants received an extra 100 shillings.

Every player was also assigned to either the private treatment or one of two public information treatments, the public treatment or the price treatment. Participants assigned to the private treatment were able to keep their investment income secret: the decisions they made in the experiment were never disclosed to other participants. In contrast, those assigned to the public treatment were required to make an announcement revealing how much they had invested in the risky security, and whether their investment was successful, to all of the other participants at the end of the experiment. The amounts that subjects invested in the zero-interest savings technology were never revealed, so those who received the larger amount could choose whether to invest 80 shillings or less so as to obscure their endowment size. Finally, those assigned to the price treatment were obliged to make the public announcement revealing their investment returns unless they preferred to pay a price, $p$, to avoid making the announcement. Prices ranged from 10 to 60 shillings, and were randomly assigned to subjects in the price treatment. Subjects were informed what price they faced before making their investment decisions, but decided whether to pay the

---

5Experimental sessions were conducted between August 3 and October 1, 2009. We report dollar amounts using the exchange rate 75.9 shillings to the dollar, which is the average over that period. The two endowments were equivalent to 1.05 and 2.35 U.S. dollars, respectively. For comparison, the median monthly wage among subjects in full-time, unskilled employment is 2000 shillings (26.35 U.S. dollars).

6Variants of this portfolio choice design have been used for at least two decades in experimental economics, though without the six treatments to which we assign participants. Earlier examples include Loomes (1991), Alm, Jackson, and McKee (1992), Gneezy and Potters (1997), and Choi, Fisman, Gale, and Kariv (2007).

7Subjects were informed up front that they were allowed to delegate the task of making the public announcement to a member of the research team if they wished to avoid the public speaking aspect of the announcement process.
price after investment returns were realized. Hence, subjects in the price treatment were not always able to afford to buy out: those who invested and lost a large fraction of their endowment did not always have enough experimental income left to pay the exit price, $p^8$.

Random assignment to treatment generated exogenous variation in the observability of investment returns and created costly opportunities to hide income. Assignment to the public information treatments meant that outcomes were verifiable, and might therefore facilitate risk-pooling and, consequently, risk-taking. On the other hand, if subjects face social pressure to share income with neighbors and kin, they might be willing to pay for obscurity when returns are visible.$^9$ In particular, the experiment creates two mechanisms through which subjects could incur a cost to hide income from others. First, those receiving the larger endowment could keep their endowment size secret by investing no more than 80 shillings. Second, subjects in the price treatment could pay the randomly assigned price, $p$, to conceal their income entirely.

### 2.2 Experimental Procedures

Experiments were conducted in 26 rural, predominantly agricultural communities in western Kenya.$^{10}$ One day prior to each experimental session, the survey team conducted a door-to-door recruitment campaign, visiting as many households within the village as possible.$^{11}$ All households within each village were invited to send members to participate in the experimental economic game session the following day. 80.4 percent of households contacted prior to the sessions chose to participate.$^{12}$ Experimental sessions were conducted in empty classrooms at local primary schools. Sessions included an average of 83 subjects; no session included fewer than 65 or more than 100 subjects. Each session lasted approximately three hours.

Within each session, participants were stratified by gender and education level (an indicator for having done any post-primary education). There were six experimental treatments, corresponding to the three information conditions (private, public, price) interacted with the two endowment sizes. Within each stratum, players were randomly assigned to

---

$^8$ Subjects were never allowed to use money from outside the experiment to pay to avoid the public announcement.

$^9$ Our design is related to those of Barr and Genicot (2008), Attanasio, Barr, Cardenas, Genicot, and Meghir (2012), and Ligon and Schechter (2012), who also use experiments which capture the desire to avoid social sanctions outside the lab.

$^{10}$ Communities were selected to be at least five kilometers apart from one another, to prevent overlap in subject populations, and to avoid areas where IPA–Kenya had ongoing projects.

$^{11}$ When the recruitment team was unable to contact and survey a household prior to the experiment, village elders were asked to invite them to attend the subsequent experimental session.

$^{12}$ In Table 1 of Appendix III (online), we examine the correlates of choosing to send a household member to the experimental session. Participants were broadly representative of the overall population, though as expected larger households were more likely to send a member to the experiment. Women from poorer households and those with relatively higher math skills were more likely to attend. Men were more likely to attend if they attended church the previous week. Subjects in more isolated communities — as measured by distance from a paved road — were more likely to participate, though this cannot bias our results since assignment to treatment occurs within villages.
each of the six treatments with equal probability\textsuperscript{13}. Players assigned to the price treatments were subsequently assigned a random price from the set of multiples of ten between 10 and 60\textsuperscript{14}.

Experimental sessions were structured as follows. After a brief introduction, enumerators read the instructions and answered participant questions, illustrating the decisions that a subject might face with a series of wall posters\textsuperscript{15}. Subjects were then called outside one at a time, by ID number, to make their investment decisions\textsuperscript{16}. Enumerators began by asking a series of questions designed to make sure that subjects understood the experiment. Subjects were then informed whether they had received the large or small endowment and whether they were assigned to the private, public, or price treatment. Those assigned to the price treatment were also told what price they would need to pay if they wished to avoid the public announcement. Subjects then made their investment decisions: each subject was handed a number of 10 shilling coins equivalent to her endowment; the participant divided these coins between a “savings” cup and a “business” cup\textsuperscript{17}. After recording a subject’s investment decision, the enumerator would give the subject a one shilling coin to flip\textsuperscript{18}. The outcome of the coin toss determined whether the money placed in the business cup was multiplied by five or removed from the subject’s final payout. Subjects assigned to the price treatment were then asked whether they wanted to pay the fee to avoid announcing their investment results. If they had enough money left to pay the fee, and they chose to do so, it was deducted from their payoff. After all decisions had been recorded, public announcements were made. Each subject received her payout in private at the end of the session, and was allowed to leave immediately after receiving her money. Figure 1 summarizes the progression of activities within the experiment.

2.3 Experimental Subjects

Sessions were conducted in Kenya’s Western Province, in three adjoining districts: Bunyala, Samia, and Butula. All three districts are predominantly smallholder farming communities, though Samia and Bunyala also have ports on Lake Victoria. Summary statistics on experimental subjects are presented in Table 1. 61 percent of subjects were female.

\textsuperscript{13}The first experimental session did not include the two price treatments, so players were assigned to each of the other four treatments with equal probability.

\textsuperscript{14}Note that each session included subjects assigned to all three information conditions, so it was impossible to infer which individuals chose to pay to avoid the public announcement, since these subjects could not be distinguished from those randomly assigned to the private treatments.

\textsuperscript{15}Detailed instructions are included in Appendix II (online).

\textsuperscript{16}Since some participants had limited literacy skills, decisions were recorded by members of the research team. To ensure that earnings not announced publicly remained private information, each enumerator sat at a desk in an otherwise empty section of the schoolyard.

\textsuperscript{17}The two cups made of plastic and were identical in size and color.

\textsuperscript{18}To limit the possibility of influencing the outcome of the coin flip, each subject placed the coin into a sealed, opaque container which she shook vigorously before opening it to reveal the outcome of the coin toss.
Respondents ranged in age from eighteen to 88. 9.4 percent of subjects had no formal schooling, while 12.2 percent had finished secondary school. The median participant was a 34 year old married woman with seven years of education, living in a six-person household with her husband and her four children. 23.0 percent of respondents live in households with at least one employed household member; most (64.6 percent) employed subjects do agricultural work or other unskilled labor. The median monthly wage among participants with full-time employment was 2,050 Kenyan shillings, or 1.35 USD per day (assuming twenty work days per month). 35.0 percent of subjects operate their own business enterprise, but only 11.6 percent of these businesses have any employees. 16.7 percent of participants have bank savings accounts\textsuperscript{19} and 52.8 percent are members of rotating savings and credit associations (ROSCAs)\textsuperscript{20}.

Most experimental subjects in our sample live amongst their kin, and are embedded in interhousehold transfer networks. The median participant has seven relatives living outside her household but in the same village. 43.8 percent of subjects had received a transfer in the last three months, while 89.8 percent report making a transfer to another household over the same period\textsuperscript{21}. In the three months prior to being surveyed, 42.4 percent of subjects’ households had been asked for a gift or loan, and 89.7 percent of households had contributed money to a “harambee,” a local fundraising drive\textsuperscript{22}.

Table 1 reports tests of balance across our six experimental treatments\textsuperscript{23}. The randomization was successful, generating minimal differences in observables across treatments. Of 68 tests (34 for each gender) reported, we observe only five significant differences in observables across treatments. Though the number of distant family members living in one’s village differs significantly across treatments in the sample of men, this variation is driven by outliers: the maximum number (within a treatment) of distant relatives reported to live in one’s village ranges from 72 to 154. A quantile regression of the median num-

\textsuperscript{19} Dupas and Robinson (forthcoming–a) found that less than 3 percent of the daily wage earners sampled in Bumala, Kenya, had savings accounts. While Bumala is just a few kilometers from the region where the present study took place, their data were collected over two years before our household survey.

\textsuperscript{20} Gugerty (2007) surveys ROSCA participants in Busia and Teso Districts in western Kenya; she argues that the social component of ROSCA participation helps individuals overcome savings constraints. Anderson and Baland (2002) show income-earning women living in Nairobi slums use ROSCAs to protect their savings from their husbands.

\textsuperscript{21} There are several reasons for the asymmetry between the probability of making a transfer and the probability of receiving a transfer. First, households comprising only children and/or the ill or handicapped could not participate (because only those adults who could be physically present for the session and were able to hear the oral instructions could take part), but are likely to be net recipients of transfers. Another reason is that most households in any village will make a small transfer toward the funeral expenses of their neighbors; since funerals are relatively rare events, we would expect to see an asymmetry between the likelihood of giving and receiving in the short-term. Finally, transfer data are quite noisy, and households are more likely to report transfers made than transfers received (Comola and Fafchamps 2010).

\textsuperscript{22} A harambee is a self-help effort in which community members contribute money or resources to assist a particular person in need. The concept existed within a number of different tribal groups in Kenya, but was made into a national rallying cry by Kenya’s first president, Jomo Kenyatta (Ngau 1987).

\textsuperscript{23} We show that the randomization of the price of avoiding making an announcement was successful, though the randomization was not stratified, in Table 2 of Appendix III (online).
ber of distant family members on the set of treatment dummies does not find significant differences across experimental treatments (results not shown). Among women attending the experiment, there is a significant difference in the number of televisions owned across treatments, and a marginally significant difference in the number of cows, but no difference in the total value of durable household assets.

3 Theoretical Framework

In this section, we outline a simple theoretical model of individual decisions within the experiment. We present decisions in a continuous, non-stochastic framework in order to derive simple comparative statics that yield testable predictions in reduced-form regressions. In Section 5, we present a discrete version of the model that aligns precisely with the (finite set of) choices subjects faced, and allows us to recover the structural parameters of interest through maximum likelihood estimation.

3.1 Individual Decisions in Private Information Treatments

In all treatments, individual $i$ divides her budget of $m_i \in \{m_s, m_l\}$ between the risky business cup and the savings cup, a risk-free savings technology. When income is private, $i$ seeks to maximize

$$E[u_i(b_i|m_i)] = \frac{1}{2}u_i(m_i - b_i + c_i) + \frac{1}{2}u_i(m_i + 4b_i + c_i),$$

where $b_i$ is the amount invested in the risky security and $c_i$ is background consumption or permanent income. We assume that individual preferences can be represented by a utility function of the CRRA form with parameter $\rho_i \geq 0$, which is private information, and that background consumption, $c_i$, is equal to zero. The scale invariance property of the CRRA utility function with $c_i = 0$ is consistent with data from the private information treatments: subjects allocate an average of 51.8 percent of their budgets to the business cup in the private treatment when they receive the smaller endowment, versus 51.9 percent when they receive the larger endowment.\footnote{A Mann-Whitney test fails to reject the null hypothesis (p-value 0.865) that the fraction of the budget invested does not depend on the budget size. There is, however, suggestive evidence that women invest a slightly larger fraction of their budgets when they receive the larger endowment (53.5 versus 50.7 percent invested) while men invest slightly less (49.3 versus 53.6 percent). Since these differences are quite small in magnitude, we restrict attention to the CRRA case.} We further assume that income is observable whenever an individual is known to have received it with probability one, as in Ashraf (2009) and Goldberg (2010); income is unobservable whenever a person can plausibly deny having received it. In the private information treatments, a subject can claim to have invested her income and lost it, limiting the potential for social pressure to share payouts.
Given these two assumptions, the amount invested in the business cup by individual $i$ in the private information treatment is given by

$$b_{i}^{pri} = \left(\frac{4^{1/\rho_{i}} - 1}{4^{1/\rho_{i}} + 4}\right) m_{i}.$$ (2)

Thus, the proportion of the budget invested depends on $\rho_{i}$, but not on the size of the budget. The proportion of $m_{i}$ invested decreases with $\rho_{i}$.

3.2 Individual Decisions in Public Treatments

Next, we consider how individual $i$’s optimization problem changes when she is obliged to stand up and announce her investment income. After making the public announcement, individuals may face social pressure to share observable income. Following Ashraf (2009) and Goldberg (2010), we assume that individual $i$ is obliged to transfer a proportion, $\tau_{i}$, of observable income to members of her social network — for example, her spouse or her relatives — and that income is observable when an individual is known to have it with probability one, whether it is announced or not. Within the experiment, the implication is that a subject assigned to the public treatment who receives the smaller endowment, $m_{s}$, cannot hide any of her income, since every subject is known to have received at least $m_{s}$ and she is forced to announce whether her investment succeeded. In contrast, an individual assigned to the private treatment can plausibly claim to have invested and lost all or most of her endowment, and a subject receiving $m_{l} = m_{s} + d$ can choose to invest $b \leq m_{s}$, thereby making $d$ shillings of income unobservable.

Proposition 1 characterizes the behavior and welfare of subjects receiving the smaller endowment, $m_{s}$, in the public treatment. Because all subjects are known to have received at least $m_{s}$, no investment strategy can obscure her total payoff. As demonstrated in the proof of Proposition 1, individuals receiving the small endowment therefore make the same allocation decisions regardless of whether investment returns are public or private. This prediction is tested in Section 4.

Proposition 1. If individual $i$ receives the small endowment, $m_{s}$, then her optimal business investment in the public treatment is equal to her optimal investment in the private treatment:

$$b_{i,s}^{pub} = b_{i,s}^{pri} = \left(\frac{4^{1/\rho_{i}} - 1}{4^{1/\rho_{i}} + 4}\right) m_{s}.$$  

Expected utility is lower in the public treatment than in the private treatment when $\tau_{i} > 0$. Expected utility is decreasing in $\tau_{i}$ for all $\tau_{i} \in [0,1]$.

Subjects who receive the large endowment have the option of investing an amount

---

25 See De Mel, McKenzie, and Woodruff (2009) for a closely related modeling approach.
less than or equal to \(m_s\), thereby creating “plausible deniability” and making themselves indistinguishable from those who received the small endowment. This discrete change in observable income means that both utility and marginal utility are discontinuous at \(b = m_s\). Recall that \(d = m_l - m_s\). As is shown in the proof of Proposition 2, an individual who invests \(b > m_s\) in the public treatment will choose

\[
b^*_{i,l} = \left(\frac{4^{1/\rho_i} - 1}{4^{1/\rho_i} + 4}\right) (m_s + d), \tag{3}
\]

the same amount she would have invested in the private, large endowment treatment. However, since utility is lower in the presence of social pressure to share observable income, such individuals will prefer to set \(b_{i,l} = m_s\) when \(\tau_i\) is sufficiently large. Proposition 2 characterizes this pattern.

**Proposition 2.** There exists a threshold risk aversion parameter, \(\rho\), such that if \(\rho_i \leq \rho\), then:

1. i’s optimal investment in the private, large endowment treatment, \(b^{pri}_{i,l}\), exceeds \(m_s\);
2. i’s optimal investment in the public, large endowment treatment takes one of two values:
   \[
b^{pub}_{i,l} \in \{m_s, b^{pri}_{i,l}\}, \tag{4}
   \]
3. and, finally, there exists \(\tau(\rho_i) \in (0,1)\) such that \(b^{pub}_{i,l} = m_s\) if and only if \(\tau_i \geq \tau(\rho_i)\).

Proposition 2 demonstrates that individuals with sufficiently low levels of risk aversion, who would invest more than \(m_s\) in the private, large endowment treatment, will either do the same in the public treatment or will invest exactly \(m_s\), the highest level of investment which keeps endowment size hidden. Whether the latter strategy is optimal depends on the level of social pressure to share one’s winnings.

In contrast, an individual who invests \(b \leq m_s\) in the public, large endowment treatment will not reveal the size of her endowment. As is shown in the proof of Proposition 3, the optimal investment is then given by:

\[
b^*_{i,l} = \left(\frac{4^{1/\rho_i} - 1}{4^{1/\rho_i} + 4}\right) \left(m_s + \frac{d}{1 - \tau_i}\right). \tag{5}
\]

Since \(0 < 1 - \tau < 1\),

\[
\left(\frac{4^{1/\rho_i} - 1}{4^{1/\rho_i} + 4}\right) (m_s + d) < \left(\frac{4^{1/\rho_i} - 1}{4^{1/\rho_i} + 4}\right) \left(m_s + \frac{d}{1 - \tau_i}\right); \tag{6}
\]

the implication is that sufficiently risk averse individuals, who would invest less than \(m_s\) in the private treatment, will invest more when investment returns are observable than when
they are private. Proposition 3 characterizes this pattern of behavior.

**Proposition 3.** For all $\rho_i > \underline{\rho}$, there exists a threshold social pressure parameter, $\bar{\tau}(\rho_i)$ such that:

1. $i$’s optimal investment in the public, large endowment treatment, $b_{i,l}^{\text{pub}}$, falls in the interval:
   
   $$b_{i,l}^{\text{pub}} \in (b_{i,l}^{\text{pri}} : m_s)$$

   if and only if $\tau_i < \bar{\tau}(\rho_i)$;

2. otherwise, for all $\rho_i > \underline{\rho}$ and $\tau_i \geq \bar{\tau}(\rho_i)$, $b_{i,l}^{\text{pub}} = m_s$.

Propositions 2 and 3 partition $(\rho_i, \tau_i)$ space into four cases which are depicted in Figure 2. Whether individuals receiving the large endowment invest above or below $m_s$ in the private treatment depends on risk aversion: individuals with $\rho_i < \underline{\rho}$ invest above $m_s$ in the private treatment (Regions C and D in Figure 2), while those with $\rho_i > \underline{\rho}$ invest below $m_s$ (Regions A and B in Figure 2). The formula for $\rho$ is given in Appendix Equation 39; $\rho$ equals $\ln(4)/\ln(5) \approx 0.861$ for the endowment sizes used in our experiment.

As described in Proposition 2, less risk averse types facing significant social pressure to share income (Region C) invest less in the public, large endowment treatment than they do in the private, large endowment treatment: they reduce their investment to exactly $m_s$. When $\rho_i < \underline{\rho}$ and $\tau_i$ is sufficiently small (Region D) investment decisions are not affected by assignment to the public treatment. However, more risk averse types facing any nonzero social pressure (Regions A and B) increase investment when returns are announced publicly. This is because the first-order condition characterizing optimal investment changes when only a portion of income is taxed, as shown in Inequality 6 and described in Proposition 3. How much risk averse types increase investment depends on the levels of social pressure and risk aversion: those facing lower social pressure (Region A) invest more when investment returns are announced publicly; but since less than $m_s$; those facing higher social pressure (Region B) shift up to exactly $m_s$ in the public treatment.

To summarize, for any given individual, the treatment effect of assignment to the public treatment is ambiguous. In practice, we expect risk preferences to be heterogeneous (Binswanger 1980, Choi, Fisman, Gale, and Kariv 2007); as a result, the predictions of the model will depend on the average treatment effect within a population with a distribution of $\rho_i$ parameters. Taken together, Propositions 2 and 3 clearly indicate that the proportion of subjects investing exactly $m_s$ (i.e. 80 shillings) will be weakly higher in the public, large

---

26 The boundary between Regions C and D is given by the relationship between $\tau$ and $\rho$. Along this boundary, the utility-maximizing investment above $m_s$, given in Equation 3, yields the same utility as investing exactly $m_s$ (thereby hiding $d$). This boundary does not appear analytically tractable, but can be calculated numerically.  
27 Along the boundary between A and B, $\bar{\tau}$ can be expressed analytically by solving for $\bar{\tau}$ as a function of $\rho$ (for $\rho > \underline{\rho}$) for which the interior solution maximizing utility conditional on investing at most $m_s$, shown in Equation 5, is to invest exactly $m_s$. The formula for $\bar{\tau}$ is given in Appendix Equation 60.
endowment treatment than in the private, large endowment treatment. The fraction investing exactly \( m_s \) will, in fact, be strictly higher if the population contains individuals in regions B or C of Figure 2. Moreover, under relevant distributions of \( \rho \), \( E[b_i^{\text{pub}} - b_i^{\text{pri}}] < 0 \) when \( \tau > 0 \). Intuitively, because subjects in region C of Figure 2 make larger adjustments to their investment level than those in region B, the overall impact of the public treatment on average investment is negative for well-behaved distributions centered at or below \( \rho \). Both of these predictions are tested in Section 4.

### 3.3 Individual Decisions in Price Treatments

We now consider individual decisions in the price treatments, where subjects can choose to pay a randomly chosen price, \( p > 0 \), to avoid making the public announcement. Observe that subject \( i \) receiving gross payout \( x_i > 0 \) in the small endowment treatment prefers to pay \( p \) whenever

\[
\frac{(x_i - p)^{1-\rho_i}}{1 - \rho_i} \geq \frac{(1 - \tau_i)^{1-\rho_i} x_i^{1-\rho_i}}{1 - \rho_i},
\]

or \( p \leq \tau_i x_i \). Similarly, a subject in the large endowment treatment prefers to pay \( p \) to avoid the public announcement whenever

\[
\frac{(x_i - p)^{1-\rho_i}}{1 - \rho_i} \geq \frac{[(1 - \tau_i) x + \tau_i d \cdot 1\{b_i \leq m_s\}]^{1-\rho_i}}{1 - \rho_i},
\]

or \( p \leq \tau_i x_i - \tau_i d \cdot 1\{b_i \leq m_s\} \). It is apparent that, for any fixed \( 0 \leq \bar{p} < x \) that makes \( i \) exactly indifferent between paying \( \bar{p} \) and making the public announcement, \( i \) strictly prefers to pay \( p \) for all \( p < \bar{p} \) and strictly prefers not to for all \( p > \bar{p} \). Similarly, for any fixed \( \bar{x} \) which makes \( i \) strictly prefers to pay \( p \) whenever her payout is above \( \bar{x} \) and strictly prefers to make the public announcement whenever her gross payout is below \( \bar{x} \). Hence, we need only consider three strategies for subjects in the price treatments: always paying \( p \) to avoid the public announcement, never paying \( p \), and paying \( p \) when the investment is successful, but not when it is unsuccessful.

When \( p \) is sufficiently high, never paying \( p \) is the optimal strategy, and individual investment decisions will be identical to those in the public treatments. For example, consider a subject in the small endowment treatment facing a \( \tau \) of 0.10 who invests half her endowment in the business cup. If her investment is successful, her gross payout is 240

\[28\text{An overly conservative condition under which } E[b_i^{\text{pub}} - b_i^{\text{pri}}] < 0 \text{ is that } Pr[\rho < \bar{\rho}] = 1 \text{ and } Pr[\tau > \bar{\tau}(\rho)] > 0. \text{ The necessary condition, however, is that most of the mass of the } \rho \text{ distribution be near or below } \rho. \text{ Because we are concerned with realistic values of } \rho, \text{ we consider a range of distributions centered near the mean values (ranging from 0.53 to 0.74) suggested by the literature (Andersen, Harrison, Lau, and Rutström 2008, Harrison, Humphrey, and Verschoor 2010, Tanaka, Camerer, and Nguyen 2010): numerically, we have confirmed that } E[b_i^{\text{pub}} - b_i^{\text{pri}}] < 0 \text{ for } \rho \sim \mathcal{N}(\mu_\rho, \sigma_\rho) \text{ such that } \mu_\rho \in [0.30, 0.85], \sigma_\rho \in [0.02, 0.60], \text{ and } \tau \in [0.01, 0.50]. \]

\[29\text{In other words, it will never be optimal for a subject to pay } p \text{ when her investment is unsuccessful but not when it is successful. In Section 5 we refer to these strategies as always, never, and heads, respectively.} \]
shillings, so she would be indifferent between announcing her investment return and paying a price of 24 shillings to avoid the announcement. For higher values of \( p \), her investment decisions will be the same as in the public treatments.

When \( \tau_i > 0 \) and \( p \) is sufficiently low, always paying \( p \) to avoid the public announcement is optimal. In this case, the optimal investment level is given by

\[
 b_i^\text{always} = \left( \frac{4^{1/p} - 1}{4^{1/p} + 4} \right) (m_i - p).
\]  

(10)

Hence, investment levels are equivalent to those in the private information treatments, but with a smaller budget of \( m_i - p \), accounting for the fact that subjects always plan to pay \( p \) to avoid making the announcement. Following directly from Equation (10), we can see that for those subjects who plan to always pay to avoid making the public announcement, optimal investment levels are decreasing in \( p \).

For intermediate values of \( p \) and \( \tau > 0 \), it is optimal to follow a strategy of paying to avoid the announcement only when the investment succeeds. Predictions in this setting are less clear-cut, and we defer consideration of this case to Section 5.

3.4 Extensions to the Model

In this section, we explore the possibility that individual behavior in the public information treatments might be influenced by factors other than social pressure to share income. We consider two such alternative explanations. First, we discuss the hypothesis that subjects might be willing to pay to avoid the public announcement because they are averse to attention or public scrutiny. We refer to this as “attention aversion.” We then explore the possibility that risky behaviors — including investing in the business cup — might be socially sanctioned.

3.4.1 Attention Aversion

A straightforward model of participants’ desire not to draw attention to themselves — without regard to any effective taxation — is to incorporate an additive cost parameter, \( \kappa \), into the utility function:

\[
 u_i^{\text{attention}}(x) = \begin{cases} 
 u_i(x) & \text{if no announcement is made} \\
 u_i(x) - \kappa & \text{if public announcement occurs}
\end{cases}
\]  

(11)

This parameter, \( \kappa \), does not affect the first order condition characterizing the optimal allocation decision. It will therefore have no impact on the likelihood of investing exactly 80 shillings in either the public treatment or the price treatment (when the price of giving is high). In light of this, our reduced-form results on investment decisions are evidence of
social pressure, and cannot be driven by the desire to avoid public attention. However, within the price treatment, \( \kappa > 0 \) would influence the willingness to pay to avoid making the public announcement. We return to this point in Section 5 when we explicitly estimate the \( \kappa \) parameter to test whether it drives decisions in the price treatments.

### 3.4.2 Social Sanctions Against Risk-Taking

Another alternative hypothesis is that differences in investment choices between the private and public information treatments stem from the desire to avoid potential social sanctions against risk-taking — for example, if investing in the business cup were perceived as similar to gambling. We made it clear to participants that there was no way for them to realize an actual loss during the experiment, and used the “business cup” framing to push this point more subtly. However, we can also examine the data for patterns that would suggest that participants were concerned about hiding the riskiness of their investments.

We consider two possible strategies for modeling social sanctions against risk-taking. First, if investing any positive amount were seen as gambling and subjects wished to avoid being observed taking such risks, we should see a larger fraction of participants choosing to invest zero in the public information treatments than in the private treatments. Alternatively, if the size of the sanction against gambling were increasing in the amount invested in the business cup, this would add a downward sloping cost to the expected utility function, thereby reducing the optimal investment amount, \( b^* \). This would lead to an overall reduction in investment levels in the public information treatments relative to the private treatments, and a particularly strong move away from large investment amounts if the function were convex; however, this would not lead to an increase in the proportion of subjects investing exactly the amount of the small endowment.

### 4 Results

In this section, we characterize individual choices within the experiment and estimate the impacts of observability on investment decisions and final payoffs. We report results relating to investment decisions in Section 4.1 and describe decisions regarding whether to pay to avoid the public announcement in Section 4.2.

Summary statistics on outcomes in the experiment are presented in Table 2. Subjects earned an average of 3.16 US dollars (240 Kenyan shillings) in the experiment, which is equivalent to eight percent of mean monthly wages among subjects reporting paid employment. Thus, stakes were large, but not life-altering. There is substantial variation in payoffs across treatments: subjects in the public, small endowment treatment received the lowest average payoffs (1.83 US dollars); those in the private, large endowment treatment earned the most (4.68 US dollars).
4.1 Individual Investment Decisions

On average, subjects chose to invest just over half their endowment in the business cup (Table 2). The fraction of the endowment invested is similar in the large and small endowment treatments. Among those receiving the larger endowment, the amount invested is slightly lower in the two public information treatments (the public and price treatments) than in the private treatment. When allotted 180 shillings, subjects could avoid revealing that their endowment exceeded that of others by investing 80 shillings or less; the probability of doing so is higher in the public information treatments than in the private treatment.

We present histograms of investment decisions in Figure 3. Dark bars represent the distribution of investment decisions in the private treatments; lighter bars represent investment decisions in the two public information treatments. As predicted by the model, decisions are similar in the public and private small endowment treatments. However, women receiving the large endowment are more likely to invest exactly 80 shillings in the public information treatments than in the private, large endowment treatment. A Kolmogorov-Smirnov test rejects the hypothesis that the two distributions are equal (p-value 0.068). There is no difference in behavior across treatments among men receiving the large endowment (p-value 0.950).

We now examine the impact of observability on investment decisions in a regression framework, estimating the effects of assignment to one of the public information treatments on the amount of money invested in the business cup. We estimate the OLS regression:

\[ Investment_{itv} = \alpha + \beta_1 Public_i + \beta_2 Large_i + \beta_3 Public \times Large_i + \eta_v + X_i' \zeta + \varepsilon_{itv} \] (12)

where \( Investment_{itv} \) is the amount invested in the business cup by subject \( i \) assigned to treatment \( t \) in village \( v \), \( Public_i \) is an indicator for assignment to one of the public information treatments, \( Large_i \) is an indicator for receiving the large endowment, \( Public \times Large_i \) is an interaction between \( Public_i \) and \( Large_i \), \( \eta_v \) is a village fixed effect, and \( X_i' \) is a vector of individual controls including dummies for age and education categories, marital status, household size, and the log value of household durable assets.\(^{30}\) Standard errors are clustered at the village level in all specifications.

Results, disaggregated by gender, are reported in Table 3. Odd-numbered columns report regression results without controls; even-numbered columns include them. The \( Public \times Large_i \) interaction is negative and significant among women (Columns 1 and 2), but positive and insignificant among men (Columns 3 and 4). The coefficient estimates indicate that women receiving the large budget invest approximately 6.3 shillings, or 6.5 percent, less when returns are observable than when they are hidden. Adding village

\(^{30}\) As discussed in Section 3, decisions in the price treatments will be identical to decisions in the public treatments when \( p \) is sufficiently high, so we pool data from both public information treatments to maximize power. Coefficient estimates are similar when data from the price treatments is omitted.
fixed effects and additional controls has almost no impact on estimated coefficients and significance levels.

Next, we test whether the observed changes in investment levels are consistent with women attempting to obscure the size of their endowments. We test the hypothesis, predicted by the model, that subjects are more likely to invest exactly 80 shillings when investment returns are observable by estimating probit regressions of the form

$$\Pr [Investment = 80] = \Phi (\alpha + \beta Public_i + X_i'\zeta)$$

among the sample of subjects assigned to the large endowment treatments, as well as a linear probability model (LPM) where the dependent variable is an indicator for investing exactly 80 shillings (Table 4, Panel A). In all specifications, women are significantly more likely to invest exactly 80 shillings in the public information treatments. For example, the LPM estimates indicate that women are 6.2 to 7.0 percentage points more likely to invest 80 shillings when investment returns are observable. The coefficient on Public in the sample of men is not significant in any specification, in line with our previous results.

Moving beyond the precise predictions of the model presented in Section 3, we also estimate similar specifications using indicators for investing either 70 or 80 shillings (Table 4, Panel B) and for investing any amount less than or equal to 80 shillings (Table 4, Panel C). Since only 2.3 percent of women and 6.0 percent of men in the private, small endowment treatment actually invest 80 shillings, subjects might feel that investing 70 shillings better obscures the size of their endowment.

In more general terms, any investment level less than or equal to 80 shillings obscures the size of the subject’s endowment, and may be seen as consistent with a desire to hide a portion of the large endowment from others. In all specifications, the Public variable is positive and significant in the sample of women, but insignificant in the sample of men. Women receiving the large endowment are between 7.0 and 7.6 percentage points more likely to invest 70 or 80 shillings and between 9.6 and 10.5 percentage points more likely to invest 80 shillings or less than those in the private, large endowment treatment.

4.1.1 Treatment Effect Heterogeneity

Our hypothesis is that women face social pressure to share income, and this creates an incentive to hide investment returns when possible, even if it is costly to do so. Under this hypothesis, the extent of income hiding should be associated with factors predicting the level of social pressure an individual is likely to face after the experiment. We focus on close kin outside the household as the group most likely to pressure individuals into sharing

---

31Investing less than, but not exactly 80 shillings may reflect level-k reasoning, along the lines first discussed by Nagel (1995), Stahl and Wilson (1994), and Stahl and Wilson (1995).
We test this by interacting the Public variable with indicators for whether or not a subject had any close kin attending the experiment, thereby disaggregating the impact of the public information treatments. We estimate the OLS regression equation

\[ Y_{itv} = \alpha + \beta_1 KinPresent_i + \beta_2 Public \times KinPresent_i + \beta_3 Public \times NoKinPresent_i + \eta_v + X_i'\zeta + \varepsilon_{itv} \] (14)

where \( Y_{itv} \) is one of three outcomes of interest: investment level, an indicator for investing exactly 80 shillings, or an indicator for investing no more than 80 shillings. We restrict the sample to subjects assigned to the large endowment treatments, who could obscure the size of their endowment by investing 80 shillings or less. We include village fixed effects (\( \eta_v \)) and controls for age and education categories, HH size, marital status, and household durable asset holdings in all specifications.

Results are reported in (Table 5, Panel A). Women with close kin attending the experiment invest less in the public information treatments and are more likely to invest exactly 80 shillings and no more than 80 shillings. The coefficient estimates are extremely large. Women with relatives present invest 24.5 shillings less (p-value 0.0175) when investment returns are observable than when they are hidden, which is equivalent to more than a twenty percent reduction in investment relative to the private information treatment. These women are also 14.9 percentage points more likely to invest exactly 80 shillings (p-value 0.0491) and 41.8 percentage points more likely to invest 80 shillings or less (p-value 0.0012). In contrast, point estimates are smaller and not statistically significant for women with no kin attending the experiment. As expected, we also find no statistically significant results for men.

An alternative hypothesis is that kin are relevant because they pass information about wives’ incomes to their husbands. This is of particular concern because 76.5 percent of women in our sample are married, and the two main ethnic groups in the area — the Luhya and the Luo — are both patrilocal (Brabin 1984, Luke and Munshi 2006), so married women typically live near their in-laws rather than their blood relatives. We present two pieces of evidence which suggest that kin are not simply conveying information to husbands.

First, we estimate Equation 14 replacing the kin variables with indicators for whether

---

32 Hoffman and Sen (2006) highlight the role played by kin networks in extracting surplus from successful relatives, while Baland, Guirkinger, and Mali (2011) provide evidence that individuals seek to hide income from family members.

33 We define close kin as parents, grandparents, siblings, grown children, and aunts and uncles. Note that we were unable to stratify treatment assignment by kin presence because the variable was constructed after experimental sessions took place using a name-matching algorithm.

34 We estimate linear probability models for the two binary outcomes. Probit results are similar in magnitude and significance, and are omitted to save space.

35 Robinson (2012) and Ashraf (2009) document limited commitment and observability effects within the household, while Anderson and Baland (2002) argue that Kenyan women use ROSCAs to hide savings from their husbands.
or not a subject’s spouse attended the experiment (Table 5, Panel B). If kin were only important because they shared information with husbands, we would expect the direct effect of a husband’s presence to be at least as large as the impact of having kin at the experiment. However, we find that the interaction between Public and the indicator for having a spouse present is not significantly associated with the amount invested or the probability of investing either exactly 80 shillings or 80 shillings or less. Moreover, the Public × NoSpousePresent variable is significantly associated with the probability of investing exactly 80 shillings and 80 shillings or less, suggesting that the main impact of the public treatment is on women whose husbands were not present.

We also examine investment decisions among the small sample of women receiving the large endowment who are not married and have close kin attending the session. These women invest an average of 95.7 shillings in the private treatment versus 84.0 shillings in the public information treatments, and they are 51.4 percentage points more likely to invest 80 shillings or less in the public treatments. These differences are not statistically significant in this twelve subject sub-sample, but it nonetheless appears that women with kin present are concerned about observability even in cases where the kin cannot possibly pass information on to husbands.

4.1.2 Income Hiding across Villages

Next, we explore the association between the level of income hiding, aggregated within a community, and village-level outcomes. If pressure to share income does, in fact, act like a tax on investment returns, we would expect to see a correlation between the level of social pressure within a community and a range of development indicators. We explore this by constructing a village-level measure of income hiding motivated by the theoretical framework presented in Section 3. Among those receiving the large endowment, the model suggests that greater pressure to share income will lead to an increase in the likelihood of investing exactly 80 shillings when returns are observable. In light of this, we create a village-level measure of the extent of income hiding among women: the difference in the proportion of women investing exactly 80 shillings between the two public information, large endowment treatments and the private, large endowment treatment. Across all 26 communities, the average level of income hiding among women is 7.27 percent; the 95 percent confidence interval for the mean level of income hiding across villages is [−0.002, 0.147].

---

36 All results presented in this section are nearly identical if we use the difference between the proportion investing exactly 80 shillings in the public, large endowment treatment (only) and the proportion investing exactly 80 shillings in the private, large endowment treatment, omitting subjects who participated in the price treatment. Results are also similar if we use the difference in the probability of investing 80 shillings or less instead of the difference in the probability of investing exactly 80 shillings.

37 We also create a measure of income hiding among men, and a separate measure of income hiding among men. Unsurprisingly, the average level of income hiding among men is substantially lower, only 1.14 percent; the 95 percent confidence interval, [−0.085, 0.108], suggests that the variation in the measure of income hiding among men is...
Figure 4 plots the relationship between our measure of income hiding among women and four village-level outcome variables: the log value of durable household assets, the fraction of subjects in either formal or skilled employment, the average level of wages from paid work, and the mean share of farm households that used fertilizer in the last year.38 All estimated relationships are negative, suggesting that more income hiding is associated with lower levels of household wealth and regular employment.

We explore these relationships in a regression framework in Table 6. In Column 1, we estimate the relationship between log household durable assets and income hiding among women. In spite of the small sample size, the estimated relationship is marginally significant (p-value 0.070). In Column 2, we include village-level controls for distance to the nearest paved road, the mean education level of subjects from that community, the mean number of close relatives in the village, and the mean number of community groups in which subjects participate. After adding these controls, the estimated association between income hiding and household assets becomes slightly larger and more significant (p-value 0.0252).

In the remainder of the table, we replicate these specifications using the other three outcome variables of interest; we find similar significant, negative relationship in all specifications. Higher levels of income hiding within the experiment are associated with lower rates of skilled and formal employment and lower wages, and are also associated with substantial reductions in the probability of using fertilizer.

To interpret the magnitude of these coefficients, consider that in our sample, the standard deviation of village-level income hiding is 18.5 percentage points. Thus, a one-standard-deviation increase in income hiding is associated with 5 percent lower household assets (4.6 log points), a 21 percent lower rate of respondent employment (1.7 percentage points), one dollar lower monthly wages from work, and a 28 percent lower rate of fertilizer use (13 percentage points).

Such cross-community results do not merit a causal interpretation. Nonetheless, these findings are of interest for two reasons. First, results are consistent with the view that pressure to share income may act as a drag on savings and investment, and may therefore slow development. An alternative, though not mutually exclusive, explanation is that in the poorest areas, enforced sharing norms remain an essential tool for handling risk, and thus the pressure to share is the most acute. In either case, the evidence suggests that social pressure to share income is greatest in the worst off areas, and should be viewed as an important social factor in models of poor, rural village economies. More generally, these results go some way toward addressing the concern that behavior in lab experiments may be largely attributable to noise. In light of this and our earlier results, we focus on the associations between income hiding among women and village-level outcomes.

38 We include the last outcome in light of evidence presented in Duflo, Kremer, and Robinson (2011) and Giné, Goldberg, Silverman, and Yang (2012) that farmers in Kenya and Malawi, respectively, often plan to use fertilizer, but are unable to save the money to purchase it in the lean season.
may not be related to decisions and outcomes outside the lab (cf. Levitt and List 2007); in this case, there is a clear association between what happens within the experiment and economic outcomes outside the lab.

4.2 The Willingness-to-Pay to Hide Income

We now examine the willingness-to-pay to avoid the public announcement using data from the price treatments. Subjects assigned to the price treatments were offered the option of paying a randomly chosen price — 10, 20, 30, 40, 50, or 60 shillings — to avoid announcing their investment income to the other subjects.\footnote{Though this randomization was not stratified, it was largely successful. Table 2 in Appendix III (online) reports the results of a balance check exercise in which subject characteristics were regressed on dummies for prices 20 through 60. The price variables are jointly significant at the five percent level in only four of the 68 F-tests.} Of 690 subjects assigned to the price treatments, 627 subjects could afford to pay $p$ to avoid the public announcement, and 190 (30.3 percent of those able to pay) chose to do so. Subjects who chose to buy out paid an average price of 29.3 shillings — equivalent to an average of 15.3 percent of their gross earnings. Figure 5 plots the proportion of subjects paying to avoid the public announcement, broken down by gender, endowment size, and exit price. Subjects are generally more likely to buy out at lower prices, though this is not as evident among men receiving the large endowment.

Table 7 reports OLS regressions of the probability of paying to avoid the public announcement on exogenous factors: the randomly assigned price and indicators for receiving the large endowment and having the coin land with heads facing up. Women with more observable income are more likely to pay to avoid the public announcement: the coefficient on Heads is consistently positive and significant, suggesting that subjects with successful investments are approximately 23 percentage points more likely to pay to avoid announcing their investment return. Men, in contrast, are not significantly more likely to pay to avoid the announcement when their investments are successful. As suggested by the figures, both men and women are less inclined to buy out at higher exit prices: the coefficient on the price variable is negative and significant in all specifications.

Analysis of factors associated with willingness-to-pay is complicated by the fact that, while prices are randomly assigned, gross payouts (savings plus investment returns) are not. As the model suggests, the relationship between pressure to share income, individual risk preferences, and the unconditional probability of paying to avoid the public announcement is complicated; and we observe whether a subject pays the exit price after a particular realization of the coin flip, but not whether she planned to never buy out, buy out if her investment was successful, or always buy out. In light of this, we defer consideration of the explicit willingness to pay to Section 5.

Table 8 reports regressions of amount invested within the experiment on the price of
exit, restricting the sample to those randomly assigned to the price treatments. The model predicts that for subjects planning to pay to avoid the public announcement whether or not their investment was successful, the amount invested will be a decreasing function of the price avoiding the public announcement. Consistent with this prediction, we find that random assignment to a higher price of avoiding the public announcement is associated with significantly lower levels of investment. In contrast to our previous results, this appears true for both women (Columns 1 and 2) and men (Columns 3 and 4).

5 Estimating the Social Pressure Parameter

In this section, we estimate the magnitude of the social pressure parameter, $\tau$, while controlling for unobserved heterogeneity in individual risk aversion. As discussed above, the treatment effects reported in Section 4 demonstrate that among women $\tau$ is not equal to zero: making investment returns observable impacts individual choices. However, the magnitude of the reduced form impact does not identify $\tau$ because the treatment effect depends on an individual’s level of risk aversion. Fortunately, random assignment should ensure that the distribution of individual risk parameters in each of the six treatments is representative of the population distribution. We can therefore estimate the parameters of that distribution using data from the private treatments, and estimate $\tau$ while controlling for heterogeneity in risk aversion in a structural framework.

We model decisions in a discrete choice setting which mirrors our implementation of the portfolio choice problem in the experiment: each subject decides how many ten shilling coins to allocate to the business cup, and allocates the remainder to the savings cup. Subjects in the small endowment treatments have nine options ($0, 10, 20, \ldots, 80$), while those assigned to the large endowment treatments have nineteen ($0, 10, 20, \ldots, 180$).

In what follows, we index experimental treatments with $t$, individual subjects with $i$, and investment options with $j$ and, when necessary, $k$. We assume that subject $i$’s expected utility of investing $b_j$ is given by:

$$EU_{ij} = EV_{ij} + \varepsilon_{ij}$$

where $EV_{ij}$ denotes the explicitly-modeled expected utility of investing $b_j$ (what Train (2003) terms “representative utility”) and $\varepsilon_{ij}$ is an i.i.d. type 1 extreme value distributed preference shock. Behavior in the private treatments suggests that individuals have heterogeneous risk preferences. We assume these can be represented by a CRRA utility function, $v_i(\cdot)$, parameterized by $\rho_i$, and that individual $\rho_i$ parameters are normally dis-

---

40 Loomes (2005) refers to such error terms as “Fechner errors.” See Hey and Orme (1994) and Von Gaudecker, van Soest, and Wengström (2011) for examples of their use in modeling stochastic choices in individual decision-making experiments.
tributed with mean $\mu_\rho$ and variance $\sigma^2_\rho$. The probability that subject $i$ chooses to invest $b_j$ can then be written in the form of a mixed logit model:

$$P_{ij} = \int \left( \frac{e^{EV_{ij}/\sigma_\varepsilon}}{\sum_{k=1}^{J_t} e^{EV_{ik}/\sigma_\varepsilon}} \right) f(\rho) d\rho. \quad (16)$$

where $\sigma^2_\rho$ is proportional to the variance of $\varepsilon_{ij} - \varepsilon_{ik}$. Let $y_{ij}$ be an indicator function equal to one if subject $i$ chooses to invest amount $b_j$. The log-likelihood function for treatment $t$ can be written as:

$$LL_t = \sum_{i \in I_t} \sum_{j \in J_t} y_{ij} \ln \left[ \int \left( \frac{e^{EV_{ij}/\sigma_\varepsilon}}{\sum_{k=1}^{J_t} e^{EV_{ik}/\sigma_\varepsilon}} \right) f(\rho) d\rho \right]. \quad (17)$$

The log-likelihoods can then be summed across treatments. We simulate the log-likelihood by taking one thousand random draws from the distribution of $\rho_i$ for each individual, and maximize the simulated log-likelihood numerically.

5.1 Heterogeneity in Individual Risk Preferences

We express the CRRA utility function as

$$v(x|\rho_i) = \frac{1}{\eta_i} x^{1-\rho_i}, \quad (18)$$

where $\eta_i = 900^{1-\rho_i} - 10^{1-\rho_i}$, the difference between the utility of the highest possible payout in the experiment and the utility of the lowest strictly positive payout. Since VNM expected utility functions represent preference orderings over lotteries and are robust to positive, affine transformations, this utility function represents the same preferences as the standard CRRA formulation,

$$u(x|\rho_i) = \frac{x^{1-\rho_i}}{1-\rho_i}. \quad (19)$$

our proposed scaling generates results which are similar to those generated by the “contextual utility” model of Wilcox (2008) and the certainty equivalent procedure used in

\[41\] Results are nearly identical if we instead assume a triangular distribution for $\rho_i$, as shown in the appendix.

\[42\] When $V_{ij} = X' \beta$, $\beta$ and $\sigma_\varepsilon$ are not separately identified; $\sigma_\varepsilon$ is identified in our framework because $EV_{ij}$ is a non-linear function of parameters.

\[43\] Our implementation follows the procedures outlined in Train (2003). We implement this using the MATLAB command \texttt{fminunc} using the default Broyden-Fletcher-Goldfarb-Shanno (BFGS) updating procedure. Standard errors are calculated using the inverse Hessian.

\[44\] See Goeree, Holt, and Palfrey (2003) for a similar approach. Using the lowest possible payout, zero, is not feasible because $u(x) \to -\infty$ as $x \to 0$ for subjects with $\rho \geq 1$. Results are almost identical when $10^{1-\rho}$ is replaced with $1^{1-\rho}$ or $0.01^{1-\rho}$. 

23
Von Gaudecker, van Soest, and Wengström (2011)[45] Given this scaling, the expected utility of investing $b_j$ in the private, small endowment treatment is given by:

$$EU_{ij} = \frac{1}{2\eta_i} (m_i - b_j)^{1-\rho_i} + \frac{1}{2\eta_i} (m_i + 4b_j)^{1-\rho_i} + \varepsilon_{ij}, \quad (20)$$

where, again, $\eta_i = 900^{1-\rho_i} - 10^{1-\rho_i}$. We compare actual investment decisions in the experiments to the predictions of the model given the estimated $\mu_\rho$ and $\sigma_\rho$ parameters in Figure 1 in Online Appendix III. The figures suggest that the model successfully predicts the distribution of actual investment decisions within the experiment.

5.2 Individual Decisions when Investment Returns Are Observable

While individual $i$’s investment decision in either of the private treatments depends only on the size of $i$’s endowment and her level of risk aversion, choices in the public treatments also depend on $\tau_i$, and choices in the price treatments depend on both $\tau_i$ and $p$. In the small endowment, public treatment, the expected utility of investing $b_j$ is given by:

$$EU_{ij} = \frac{1}{2\eta_i} [(1 - \tau_i)(m_s - b_j)]^{1-\rho_i} + \frac{1}{2\eta_i} [(1 - \tau_i)(m_s + 4b_j)]^{1-\rho_i} + \varepsilon_{ij}. \quad (21)$$

Given this expression for $EV_{ij}$, the log-likelihood function is defined by Equations 16 and 17.

In the public, large endowment treatment, subjects have the option of investing 80 shillings ($m_s$) or less, thereby making 100 shillings ($m_l - m_s$) unobservable to other participants. We indicate this potentially hidden quantity as:

$$H_{ij} = (m_l - m_s) \cdot 1\{b_j \leq m_s\} \quad (23)$$

where $1\{\cdot\}$ is the indicator function. Thus, the expected utility of investing $b_j$ is given by:

$$EU_{ij} = \frac{1}{2\eta_i} [(1 - \tau_i)(m_l - b_j) + \tau_i H_{ij}]^{1-\rho_i} + \frac{1}{2\eta_i} [(1 - \tau_i)(m_l + 4b_j) + \tau_i H_{ij}]^{1-\rho_i} + \varepsilon_{ij} \quad (24)$$

[45]We defer the interested reader to Online Appendix IV, in which we discuss our scaling procedure in more detail and report the results of a sensitivity analysis.

[46]Note that, referring to Equation 20, we could re-write this as

$$EU_{ij} = (1 - \tau_i)^{1-\rho_i} EV_{ij}^{\text{private}} + \varepsilon_{ij} \quad (22).$$

As discussed earlier, the $EV$-maximizing investment choice is identical in the small endowment public and private treatments. However, scaling down the $EV$ values by $(1 - \tau_i)^{1-\rho}$ should make choices in the public treatment slightly noisier, and this is exactly what we find: the standard deviation the amount invested is 15.8 shillings in the private, small endowment treatment, and it is 16.6 shillings in the analogous public treatment.
Again, given the $EV_{ij}$ values, the log-likelihood function is defined by Equations 16 and 17.

In the price treatments, subjects first decide how much to invest, then learn their investment return, and finally decide whether to pay the price, $p$, to avoid the public announcement (if they have enough money to do so after investment outcomes are realized). The probability of any observed sequence of choices — investing $b_j$, and then deciding whether to pay $p$ to avoid the announcement — is the product of the probability of making the observed investment decision and the conditional probability of making the observed buyout decision.

As discussed in Section 3, there are three possible strategies which may be optimal for subjects in the price treatment: never paying $p$, always paying $p$, and paying $p$ only when the investment is successful. We refer to these strategies as never, always, and heads, respectively. For some values of $b_j$ and $p$, always may not be a viable strategy — for example, participant $i$ cannot plan to pay $p$ if she invests and loses her entire endowment.

The expected utility of the never strategy is defined by Equation 21 for the small endowment treatment and by Equation 24 for the large endowment treatment. The representative utilities of the always and heads strategies are defined as follows:

$$EV^{\text{always}}_{ij} = \frac{1}{2\eta_i} (m_i - b_j - p)^{1-\rho_i} + \frac{1}{2\eta_i} (m_i + 4b_j - p)^{1-\rho_i}$$

$$EV^{\text{heads}}_{ij} = \begin{cases} \frac{1}{2\eta_i} [(1 - \tau_i) (m_s - b_j)]^{1-\rho_i} + \frac{1}{2\eta_i} (m_s + 4b_j - p)^{1-\rho_i} & \text{if } m_i = m_s \\ \frac{1}{2\eta_i} [(1 - \tau_i) (m_l - b_j) + \tau_i H_{ij}]^{1-\rho_i} + \frac{1}{2\eta_i} (m_l + 4b_j - p)^{1-\rho_i} & \text{if } m_i = m_l \end{cases}$$

We assume subjects make investment decisions without knowing the realization of the preference shock which will influence their buyout decisions. Hence, subject $i$ in a price treatment chooses investment amount $b_j$ to maximize:

$$EU_{ij} = \max \left\{ EV^{\text{never}}_{ij}, EV^{\text{heads}}_{ij}, EV^{\text{always}}_{ij} \right\} + \varepsilon_{ij}.$$ (27)

Whenever $m_i - b_j < p$, $EV^{\text{always}}_{ij}$ is omitted from Equation 27.

After the investment return is realized, if $i$ has a gross payout greater than $p$, she decides whether to pay $p$ to avoid the public announcement. Given a realized gross payout of $x_i$, the utility of paying to avoid the announcement is:

$$\frac{1}{\eta_i} (x_i - p)^{1-\rho_i} + \zeta_{i0}$$

This includes $\zeta_{i0}$, participant $i$’s idiosyncratic utility from avoiding announcement given
this payout. Meanwhile, the utility of making the announcement is:

\[
\frac{1}{\eta_i} ((1 - \tau_i)x_i + \tau_i H_{ij})^{1 - \rho_i} + \zeta_{i1} \tag{29}
\]

where, analogously, \(\zeta_{i1}\) is idiosyncratic utility associated with announcing. We assume that \(\zeta_{i0}\) and \(\zeta_{i1}\) are draws from a type 1 extreme value distribution, and that they are independent of each other and of the \(\varepsilon_{ij}\) terms. Let \(e_i\) equal one if subject \(i\) chooses to pay \(p\) and zero otherwise. Now define

\[
\Delta U_{i}^{\text{exit}} = (-1)^{e_i} \left( \frac{1}{\eta_i} (x_i - p)^{1 - \rho_i} - \frac{1}{\eta_i} ((1 - \tau_i)x_i + \tau_i H_{ij})^{1 - \rho_i} \right) + (-1)^{e_i} (\zeta_{i0} - \zeta_{i1}) \tag{30}
\]

so that \(\Delta V_{i}^{\text{exit}}\) is the difference between the utility of the action that was not chosen (paying \(p\) to avoid the public announcement or not) and the utility of taking the chosen action. The probability of \(i\)'s observed sequence of actions is then given by:

\[
P_{ij} P_{i}^{\text{exit}} = \int \left( \frac{e^{EV_{ij}/\sigma_\varepsilon}}{\sum_{k=1}^{d} e^{EV_{ik}/\sigma_\varepsilon}} \cdot \frac{1}{1 + e^{\Delta V_{i}^{\text{exit}}/\gamma}} \right) f(\rho) d\rho, \tag{31}
\]

where \(\gamma^2\) is proportional to the variance of the difference between \(\zeta_{i0}\) and \(\zeta_{i1}\), the Gumbel-distributed noise parameters specific to the buy out decision.

Before proceeding to our estimates of the kin tax parameter, it is worth reviewing the sources of identification in our model. Because subjects choose from a rich menu of investment options, the distributions of investment decisions in the two private treatments allow us to identify \(\mu_\rho, \sigma_\rho, \) and \(\sigma_\varepsilon\). The kin tax parameter, \(\tau\), is identified by the differences in the distribution of investment decisions between the private, large endowment treatment and the two public information, large endowment treatments; the relationship between the willingness to pay to avoid the public announcement and observable income provides a second source of identification. Finally, the variance of the logit error term in the buy out decisions, \(\gamma^2\), is identified by the excess willingness to pay to avoid the public announcement at very low gross payouts and high exit prices; our model attributes this to the stochastic component of individual decisions.

5.3 Parameter Estimates

Summing the log likelihoods in all treatments as shown in Equation \[17\] — with \(EV_{ij}\) expressions from Equations \[20\] \[21\] \[24\] and \[27\] and the conditional probability in Equation \[31\] — we can estimate all parameters of the model using the full dataset. We do so separately for men and women, as the experimental treatment randomization was stratified
on gender to permit separate analysis. Parameter estimates are reported in Table 9. In Column 1, we report estimates from a simplified likelihood function which only uses data from investment decisions. In Column 2, we report parameter estimates based on all the decisions within the experiment.

For women, the estimated $\tau$ ranges from 0.0432 to 0.0450, and is significantly different from zero at the 99 percent confidence level. Among men, the point estimate is smaller, ranging from 0.0234 to 0.0267, and is only marginally significant. In Figure 3 we compare the predictions of the model to the actual frequency with which subjects pay to avoid the public announcement. We disaggregate the data according to the implied tax rate facing subjects: the randomly-assigned exit price they faced divided by their gross payout. In a deterministic choice model, subjects will pay to avoid the public announcement whenever $\tau_i > p_i/x_i$, where $x_i$ is their gross payout (or $\tau_i > p_i/[x_i-(m_i-m_s)]$ for subjects assigned to the large endowment treatment who invested less than $m_s$ in the business cup). However, as the figure demonstrates, the stochastic component plays a large role in individual decisions within our experiment, particularly when the difference between the expected utility of paying $p$ and the expected utility of sharing income with others is small — though the estimated $\tau$ parameter is less than 0.05, the model predicts the observed rates of paying to avoid the public announcement even when the price is more than five percent of the gross payout. For women, the estimated parameters fit the data well, though the model over-predicts the likelihood of paying $p$ at implied tax rates between 30 and 50 percent.

As discussed in Section 3, one alternative explanation for the relatively high willingness to pay to avoid the public announcement is that subjects are attention averse, and wish to avoid being asked to stand up in front of their neighbors, irrespective of whether their income from the experiment will be revealed. We explore this by incorporating an additional parameter, $\kappa$, into the model, which is simply subtracted from all $EV_{ij}$ expressions any time a public announcement is being made. Recall that $\tau$ is identified by changes in behavior across public and private treatments, and by variation in willingness to pay in price treatments with respect to observable income. In contrast, $\kappa$ is identified by excess willingness to pay in the price treatments, and its variation with respect to total income. As shown in Column 3, $\kappa$ is precisely estimated and very close to zero in the sample of women, and we cannot reject the null that $\kappa$ is zero for both women and men.

Our ability to explore potential heterogeneity in $\tau$ is limited by the relatively small samples in different demographic categories, particularly in the price treatment, where subjects faced different randomly-assigned prices and decisions depended on both prices and (not randomly-assigned) gross payouts. However, in light of our reduced form results, we take an initial step in this direction by allowing $\tau$ to depend on whether a subject’s close relatives were present at the experiment. In Table 10 we report parameter estimates when we replace the single $\tau$ with two separate parameters, $\tau_{no \ kin \ present}$ and $\tau_{kin \ present}$. Among
women, $\tau_{no\ kin\ present}$ is slightly smaller than in the full sample, at 0.043, but remains statistically significant. The estimated value of $\tau_{kin\ present}$ is 0.080 — substantially higher, and also statistically significant. Among men, as in the full sample, $\tau_{no\ kin\ present}$ remains about 2.7 percent, while the estimated $\tau_{kin\ present}$ is slightly below zero and imprecisely estimated. Thus, consistent with our reduced form results, we find evidence that women with kin present at the experiment are more exposed to social pressure to share income.

5.4 Simulations

5.4.1 Alternative laboratory experiments

The reduced form results depend on the specific parameters of the investment scenario, while the structural parameter estimates shown in Tables 9 and 10 do not. To illustrate this, we briefly show how the reduced form results would have differed with the same population, but using slightly different experimental parameters.

To simulate the experiment for women, we use the parameters in Column 2 of Table 9: $\mu_\rho = 0.7488$, $\sigma_\rho = 0.1992$, $\sigma_\varepsilon = 0.0125$, $\tau = 0.045$, and $\gamma = 0.0588$. With these values, we can simulate behavior under a variety of settings. For a simple demonstration, we consider the same laboratory experiment but with different investment returns. In the actual lab setting, as described in Section 2, the investment amount was multiplied by five when successful, and zero when unsuccessful. We simulate the experiment for a range of values of the successful investment return on the interval $[2,12]$, and show the predictions for one of the reduced form regressions — Table 4, Panel C, Columns 3 and 4. For subjects receiving the large endowment treatment, we compare behavior in the private treatment to choices in the two public information treatments, and measure the change in the probability of investing no more than the small endowment (80 shillings).

For the value 5.0, highlighted in Figure 7, the predicted change in the fraction of participants investing 80 shillings or less is 8 percentage points. This is close to the point estimates of 9.6 and 10.5 percentage points shown in Columns 3 and 4 of Table 4, Panel C. Figure 7 shows, however, that we might have seen even larger effects if successful investments had been multiplied by four rather than five, while we would have seen smaller effects if successful investments had been multiplied by three or ten, for example. The intuition behind the figure is straightforward: the largest reduced form effect is found when much of the population invests just over 80 shillings in the private treatment. Effects diminish as investment returns go up because the investment becomes so profitable that it is no longer worth sacrificing one’s expected return to hide the large endowment. On the other side, effects diminish as investment returns decline because few participants invest over 80 shillings when the risky investment has a low expected return.

Similar figures can be constructed for other reduced form results in the paper, or by
varying other features of the laboratory experiment. The key insight is that while the reduced form results would have varied across a range of closely related laboratory scenarios, the underlying structural parameters remain the same. It is these parameters that allow us to model behavior both in the lab, and beyond it.

5.5 Impacts of social pressure on entrepreneurship

Our results thus far indicate that women in the experiment behave as if they expect to be pressed to share four percent of their cash income with others, and substantially more if their close kin can observe their income directly. A 4–8 percent “kin tax” may have large disincentive effects if, for example, relatives observe wages or micro-enterprise revenues, but are not able to easily separate profits from total income by accounting for labor time and indirect costs, both of which may be unobserved\[47\] We explore this possibility by simulating a simple model of individual entrepreneurship adapted from the theoretical framework in Banerjee, Duflo, Glennerster, and Kinnan (2010). In their model, individuals receive income $y_i$ in each of two periods. $y_i$ can be seen as an individual’s income from subsistence agriculture. In the first period, each person decides whether to invest in a microenterprise which yields return

$$A(K_i - K)$$

where $K_i$ is the amount that $i$ invests in her microenterprise. To keep the model as simple as possible, we assume that individuals can neither save nor borrow. Thus, $i$ chooses $K_i$ to maximize

$$\frac{1}{\eta_i} (y_i - K_i)^{1-\rho_i} + \delta \frac{1}{\eta_i} (y_i + (1-\tau)A(K_i - K))^{1-\rho_i}.$$  \(33\)

We assume that individuals are pressed to share a proportion of their business income, but can avoid sharing their subsistence income — for example, because it may never be converted into cash.

We simulate a village economy comprising equal numbers of poor and non-poor individuals. We set $y_i = 800$ shillings for poor individuals, and $y_i = 1500$ shillings for the non-poor. These are roughly equivalent to the 30th and 70th percentiles of the rural consumption distribution in Uganda, as reported in Uganda Bureau of Statistics (2006)\[48\] We discretize the decision problem by assuming that individuals can invest any multiple of 100 shillings in a microenterprise. We do not allow individual consumption to drop to zero in any period, and we set $K$ equal to 100 shillings, so that the fixed costs of starting an

\[47\]This would be consistent with evidence that many micro-entrepreneurs are unable to calculate their own profits, and do not correctly deduct time and indirect costs (cf. Karlan, Knight, and Udry 2012).

\[48\]We were unable to find analogous statistics for rural Kenya. Beegle, De Weerdt, and Dercon (2011) report similar figures for rural Tanzania.
enterprise are quite low. We assume that individuals have heterogeneous risk preferences, and that individual CRRA parameters are normally distributed according to the mean and variance reported in Column 2 of Table 9.

We explore values of $A$ ranging from 1.5 to 2.5. For each $A$ value, we take 10,000 draws from the distribution of CRRA parameters and calculate the fraction of women who invest a positive amount in a microenterprise and the average amount invested. We report results for three values of $\tau$: when $\tau$ equals zero (i.e. in the absence of social pressure to share income), when $\tau$ is equal to 4.5 percent (as in our pooled data), and when $\tau$ is equal to 8 percent (our estimated value of $\tau$ when relatives are able to observe income streams directly). Results from the simulations are presented in Figure 8.

In the absence of kin pressure, only 1 percent of women become entrepreneurs when $A$ is equal to 1.5, while 98 percent of women become entrepreneurs when $A$ is equal to 2.5. Averaging across all values of $A$ between 1.5 and 2.5, our simulations suggest that 59.9 percent of women would become entrepreneurs in the absence of kin pressure; but that number drops to 44.2 percent when $\tau$ is equal to 8 percent. Similarly, our simulations suggest that women would invest an average of 341 shillings in their enterprises in the absence of kin pressure, but this drops to 247 shillings if $\tau$ is equal to 8 percent. Thus, an 8 percent kin tax leads to more than a 27 percent decline in overall investment.

Thus, the investment impacts of relatively small kin taxes can be quite large. However, as the figures suggest, the simulated impact of social pressure depends on the value of $A$, the return on business investment. At the highest value of $A$ we consider, 2.5, moving from a $\tau$ of zero to a $\tau$ of 8 percent reduces the fraction of women starting businesses from 0.98 to 0.97, and reduces average business investment by only 7 percent (from 598 shillings to 555 shillings). Intuitively, when entrepreneurship is profitable enough, social pressure has little effect since the return to starting a business is large even after sharing a portion of one’s revenue with kin. On the other hand, at the value of $A$ which maximizes the impact of social pressure to share, 1.94, even the relatively lower $\tau$ of 4.5 percent reduces the percent of women starting businesses from 64 to 40, and reduces average business investment by more than a third (from 349 to 232 shillings). At this level of $A$, a $\tau$ of 8 percent would have even more dramatic impacts, reducing the share of women starting businesses to only 26 percent, and reducing the average investment level by 56.7 percent. Thus, a relatively moderate level of social pressure to share can have large disincentive effects and, potentially, consequences for growth. However, the overall impacts will depend on the range of investments available to individuals, and their relative levels of observability.
6 Conclusions

We report the results of a novel economic experiment designed to measure social pressure to share income in Kenyan villages. Our approach is stratified to ensure balance, randomized within villages, and is conducted on a large sample. The design permits both reduced-form estimates to find results in line with comparative static predictions, and structural estimates to identify parameters of interest in the presence of heterogeneity.

Women who know that the outcome of their investments will be made public make investments that are less profitable in expectation. Results are strongest for those who have relatives present at the experiment. When we offer some participants the opportunity to pay a fee to avoid making an announcement, they do so at substantial cost: 30 percent of those able to pay to avoid the public announcement choose to do so; these subjects sacrifice 15 percent of their gross payout, on average. Structural estimates of the average “kin tax” are significantly different from zero for women, estimated at roughly 4.3 percent for those whose relatives did not attend the experiment, but at 8.0 percent for those with relatives present. Our model of stochastic choices in the experiment fits the data well, explaining both investment and exit decisions. We see no evidence that this behavior can be explained by household bargaining with a spouse, aversion to public announcements, or aversion to risk-taking in general.

We hypothesize that the behavior observed in this experiment is a sign that village sharing norms distort investment incentives towards less visible, but potentially less profitable, investments, and may consequently slow economic growth. The negative correlations we observe between the extent of income hiding at the village level and the level of prosperity in the village, measured several different ways, are in agreement with this interpretation. However, such results should be interpreted with caution, since the direction of causality is unclear. Moreover, the efficiency impacts of social pressure to share income will clearly depend on the range of income-hiding technologies available, and correlation between observability and profitability. There is still much to be learned about the range of observable and unobservable investment opportunities available to poor households, the set of technologies for hiding or protecting income from pressure to share, and the mechanics of that pressure. Nonetheless, simulating a simple model of entrepreneurship using our estimated structural parameters suggests that the levels of pressure to share documented in this paper may lead to large reductions in the probability of starting a business and the overall level of entrepreneurial investment. Whether the levels of social pressure we observe are large or small will depend on how social pressure is exerted outside of the lab: for example, whether individuals are pressed to share all cash income (such as business revenues) or only their profits after compensating themselves for indirect costs or labor time.

One such possibility is that individuals are not pressured to share earned income. However, Jakiela (2009) reports experimental evidence that respect for “earned property rights” is less prevalent in rural villages than in rural villages.
Studies of mutual insurance typically assume that transfer arrangements are on the efficient frontier, though the analogous assumption has been called into question in intra-household bargaining contexts. Our work suggests that relationships with close kin outside the household may be similar to within-household interactions, and that social sanctions which encourage cooperation and sharing may also have important disincentive effects.

Balance columns report p-values from F test of the joint significance of treatment dummies in a regression in which the variable listed in the first column is used as the dependent variable. Regressions are estimated separately by gender. *** indicates significance at the 99 percent level; ** indicates significance at the 95 percent level; and * indicates significance at the 90 percent level.

</table>

Standard errors in parentheses. \(*\) indicates significance at the 99 percent level; \(**\) indicates significance at the 95 percent level; and \(*\) indicates significance at the 90 percent level. LN HH Assets is the average of the log value of durable assets owned by households. Has Regular Job is the fraction of participants with formal, skilled, and/or professional employment. Wages from Work is the average of wages received from paid work over the last month in US dollars; wages are set to zero for subjects with no paid employment. Fertilizer Use denotes the fraction of households engaged in agricultural that used fertilizer over the previous twelve month period.

Standard errors in parentheses.
A Appendix

To simplify notation, we omit $i$ subscripts when there is no possibility of ambiguity.

A.1 Proofs

Proof of Proposition 1. The optimal investment level in the private, small endowment treatment can be derived from the following first order condition:

$$\frac{1}{2} \left( m_s - b_{pri}^{s} \right)^{-\rho} = \frac{4}{2} \left( m_s + 4b_{pri}^{s} \right)^{-\rho}$$

The first order condition characterizing the optimal investment level in the public, small endowment treatment can be derived from the following first order condition:

$$\frac{1}{2} \left[ (1 - \tau) (m_s - b_{pub}^{s}) \right]^{-\rho} = \frac{4}{2} \left[ (1 - \tau) (m_s + 4b_{pub}^{s}) \right]^{-\rho}.$$  \hspace{1cm} (34)

In this case, it is apparent that the $1 - \tau$ term drops out immediately, making the FOC identical to the one above. Thus, the solutions to the two FOCs must be the same: $b_{pri}^{s} = b_{pub}^{s}$. This is the first piece of Proposition 1.

The second and third pieces of Proposition 1 follow immediately. Because the same budget choice is made in the public and private treatments, the only difference in expected utility comes from the inclusion of a factor of $(1 - \tau)$ in the argument of the utility functions under each of the two possible investment outcomes. Because members of the CRRA family of utility functions are increasing functions, for $\tau \in (0, 1]$, expected utility is lower in the public treatment than in the private treatment, and for $\tau \in [0, 1]$, utility is decreasing in $\tau$.

□

Proof of Proposition 2. To arrive at Claim 1, observe that

$$\frac{\partial}{\partial \rho} b_{pri}^{l} = \left( \frac{4^{1/\rho} + 4}{4^{1/\rho} + 4} \right) m_l \ln \left( \frac{4^{1/\rho} + 4}{4^{1/\rho} + 4} \right)$$

$$= \left( \frac{-5 \cdot 4^{1/\rho} \ln 4}{\rho^2 (4^{1/\rho} + 4)^2} \right) m_l.$$  \hspace{1cm} (35)

This is clearly negative since $\rho$ and $m_l$ are positive numbers. Thus, the optimal investment in the private, large endowment treatment is decreasing in $\rho$. As is apparent from inspection of Equation (3), $\lim_{\rho \to 0} b_{pri}^{l} = m_l$, and $\lim_{\rho \to \infty} b_{pri}^{l} = 0$. Thus, signing the derivative demonstrates that $\rho$ exists. We can explicitly solve for $\rho$:

$$b_{pri}^{l} = \left( \frac{4^{1/\rho} - 1}{4^{1/\rho} + 4} \right) m_l = m_s$$

$$\Leftrightarrow \left( \frac{4^{1/\rho} - 1}{4^{1/\rho} + 4} \right) (m_s + d) = \left( \frac{4^{1/\rho} + 4}{4^{1/\rho} + 4} \right) m_s$$

$$\Leftrightarrow 2 = \frac{\ln 4}{\ln(5m_s + d) - \ln d}.$$  \hspace{1cm} (36)

Since $b_{pri}^{l}$ is decreasing in $\rho$, individuals with $\rho < \rho$ invest more than $m_s$ in the private, large endowment treatment.

To see that such individuals will either invest $b_{pri}^{l}$ or $m_s$ in the public, large endowment treatment, note that the interior solution for an optimal investment below $m_s$ which obscures the size of one’s endowment is

$$\left( \frac{4^{1/\rho} - 1}{4^{1/\rho} + 4} \right) m_s + \left( \frac{4^{1/\rho} - 1}{(1 - \tau)(4^{1/\rho} + 4)} \right) d.$$  \hspace{1cm} (37)
Since this is greater than $b^\text{pri}_i$, such an interior solution below $m_s$ is clearly not possible for individuals with $\rho < \rho_*$, for whom $b^\text{pri}_i > m_s$. This leaves them with two options: the interior solution above $m_s$ ($b^\text{pri}_i$) and the corner ($m_s$).

Finally, to arrive at Claim 3, observe that if $i$ sets her investment level at $b^\text{pri}_i$, her expected utility is

$$E \left[ u_i \left( b^\text{pri}_i | \rho, \tau \right) \right] = \frac{(1 - \tau)^{1-\rho}}{2(1-\rho)} \left( (m_i - b^\text{pri}_i)^{1-\rho} + (m_i + 4b^\text{pri}_i)^{1-\rho} \right).$$  \hspace{1cm} (41)

**Inspection of Equation (41) above reveals that:**

$$\lim_{\tau \to 1} E \left[ u_i \left( b^\text{pri}_i | \rho, \tau \right) \right] = \begin{cases} 0 & \text{if } \rho < 1 \\ -\infty & \text{if } \rho > 1 \end{cases}$$  \hspace{1cm} (42)

If, on the other hand, $i$ invests exactly $m_s$, her expected utility is

$$E \left[ u_i \left( m_s | \rho, \tau \right) \right] = \frac{1}{2} \left( \frac{d^{l-\rho}}{1-\rho} + \frac{(1 - \tau)(5m_s + d)^{1-\rho}}{1-\rho} \right)$$  \hspace{1cm} (43)

**Inspection of Equation (43) above reveals that:**

$$\lim_{\tau \to 1} E \left[ u_i \left( m_s | \rho, \tau \right) \right] = \frac{d^{l-\rho}}{1-\rho} > \begin{cases} 0 & \text{if } \rho < 1 \\ -\infty & \text{if } \rho > 1 \end{cases}$$  \hspace{1cm} (44)

Thus, combining Inequality (42) with Equation (44), we see that

$$\lim_{\tau \to 1} E \left[ u_i \left( m_s | \rho, \tau \right) \right] = \lim_{\tau \to 1} E \left[ u_i \left( b^\text{pri}_i | \rho, \tau \right) \right]$$  \hspace{1cm} (45)

But by definition,

$$E \left[ u_i \left( m_s | \rho, \tau \right) \right]|_{\tau = 0} < E \left[ u_i \left( b^\text{pri}_i | \rho, \tau \right) \right]|_{\tau = 0}$$  \hspace{1cm} (46)

Thus, by the intermediate value theorem, there must exist at least one $\tau \in (0, 1)$ such that:

$$E \left[ u_i \left( m_s | \rho, \tau \right) \right]|_\tau = E \left[ u_i \left( b^\text{pri}_i | \rho, \tau \right) \right]|_\tau$$  \hspace{1cm} (47)

To show that there is exactly one such $\tau$, we will demonstrate that

$$\frac{\partial}{\partial \tau} \left( E \left[ u_i \left( b^\text{pri}_i | \rho, \tau \right) \right] - E \left[ u_i \left( m_s | \rho, \tau \right) \right] \right) < 0$$  \hspace{1cm} (48)

This monotonicity (48) implies that $\tau$ is unique, and that $b^\text{pub}_i = m_s$ for all $\tau \geq \tau$. For compactness, we will denote the expression on the left side of inequality (48) as $\Delta^\text{EU}_{\tau}$. Taking the derivative of equations (47) and (43), we find that $2\Delta^\text{EU}_{\tau}$

$$= -(1 - \tau)^{-\rho} \left( (m_i - b^\text{pri}_i)^{1-\rho} + (m_i + 4b^\text{pri}_i)^{1-\rho} \right) + 5m_s [(1 - \tau)(5m_s + d)]^{-\rho}$$  \hspace{1cm} (49)

Because $x^{-\rho}$ is decreasing for positive $\rho$, it follows that $2\Delta^\text{EU}_{\tau}$

$$< -(1 - \tau)^{-\rho} \left( (m_i - b^\text{pri}_i)^{1-\rho} + (m_i + 4b^\text{pri}_i)^{1-\rho} \right) + 5m_s [(1 - \tau)(5m_s + d)]^{-\rho}$$  \hspace{1cm} (50)

Simplifying:

$$2\Delta^\text{EU}_{\tau} < -(1 - \tau)^{-\rho} \left[ (m_i - b^\text{pri}_i)^{1-\rho} + (m_i + 4b^\text{pri}_i)^{1-\rho} - 5m_s (5m_s + d)^{-\rho} \right]$$  \hspace{1cm} (51)

By adding $(1 - \tau)^{-\rho}(d)(5m_s + d)^{-\rho}$ to the right side, inequality (51) implies:

$$2\Delta^\text{EU}_{\tau} < -(1 - \tau)^{-\rho} \left[ (m_i - b^\text{pri}_i)^{1-\rho} + (m_i + 4b^\text{pri}_i)^{1-\rho} - (5m_s + d)^{1-\rho} \right]$$  \hspace{1cm} (52)
Now, we rely on the fact that $\rho < \bar{\rho}$, which implies

$$b^{pri}_l = \left(\frac{4^{1/\rho} - 1}{4^{1/\rho} + 4}\right) m_l > m_s$$

(53)

Let $b^{pri}_l = m_s + e$ with $0 < e < d$. Now, substituting into (42), we have:

$$-(1-\tau)^{-\rho} [(m_s + d - m_s - e)^{1-\rho} + (m_s + d + 4(m_s + e))^{1-\rho} - (5m_s + d)^{1-\rho}]$$

(54)

Simplifying, we have:

$$2\Delta'_{EU} < -(1-\tau)^{-\rho} [(d - e)^{1-\rho} + (d + 5m_s + 4e)^{1-\rho} - (d + 5m_s)^{1-\rho}]$$

(55)

Because $d, e,$ and $m_s$ are all positive, it is clear that $d - e < d + 5m_s < d + 5m_s + 4e$. If $\rho > 1$, then $x^{1-\rho}$ is decreasing, so the leftmost term is the largest. If $\rho < 1$, then $x^{1-\rho}$ is increasing, so the middle term is the largest. In either case, the sum of the three terms inside the parentheses is positive, so the expression is negative, and we have:

$$2\Delta'_{EU} < -(1-\tau)^{-\rho} [(d - e)^{1-\rho} + (d + 5m_s + 4e)^{1-\rho} - (d + 5m_s)^{1-\rho}] < 0$$

(56)

Hence, the inequality in (48) holds, and $\tau$ is unique.

\[ \Box \]

**Proof of Proposition 3.** Recall Equation (7), which states that an individual who invests $b < m_s$ will choose:

$$b^* = \left(\frac{4^{1/\rho} - 1}{4^{1/\rho} + 4}\right) m_s + \frac{(4^{1/\rho} - 1) d}{(1-\tau) \left(\frac{4^{1/\rho}}{4^{1/\rho} + 4}\right)}$$

(57)

Substituting the above into the expression $b^* \leq m_s$, and rearranging, we have:

$$\left(\frac{4^{1/\rho} - 1}{4^{1/\rho} + 4}\right) d \leq 5(1-\tau) m_s$$

$$\Leftrightarrow \tau \leq 1 - \frac{(4^{1/\rho} - 1) d}{5m_s}.$$  

(58)

(59)

Inspection reveals that

$$\tau \rho = 1 - \frac{(4^{1/\rho} - 1) d}{5m_s}$$

(60)

is increasing in $\rho$ and approaches one as $\rho$ approaches infinity. Moreover, solving the equation $\tau (\rho) = 0$ reveals that $\tau (\rho)$ is exactly zero when $\rho = \bar{\rho}$. Thus, for $\rho > \bar{\rho}$, there exists a $\tau (\rho) \in (0,1)$ such that

$$\left(\frac{4^{1/\rho} - 1}{4^{1/\rho} + 4}\right) m_s + \frac{(4^{1/\rho} - 1) d}{(1-\tau) \left(\frac{4^{1/\rho}}{4^{1/\rho} + 4}\right)} < m_s$$

(61)

whenever $\tau < \bar{\tau}(\rho)$. Individuals with $\rho > \bar{\rho}$ and $\tau < \bar{\tau}(\rho)$ who are assigned to the public, large endowment treatment will choose the optimal $b^{pub}_l$ characterized by Equation (61), thereby guaranteeing that $b^{pri}_l < b^{pub}_l < m_s$.

Otherwise, if $\rho > \bar{\rho}$ but $\tau \geq \bar{\tau}(\rho)$, $b^{pri}_l < m_s$, but

$$\left(\frac{4^{1/\rho} - 1}{4^{1/\rho} + 4}\right) m_s + \frac{(4^{1/\rho} - 1) d}{(1-\tau) \left(\frac{4^{1/\rho}}{4^{1/\rho} + 4}\right)} \geq m_s.$$

(62)

In this case,

$$\lim_{b \to m_s} \frac{\partial}{\partial b} E [u_i (b | \rho, \tau)] > 0 \text{ but } \lim_{b \to m_s} \frac{\partial}{\partial b} E [u_i (b | \rho, \tau)] < 0.$$  

(63)

As $b$ increases beyond $m_s$, the amount that individuals are pressured into sharing increases discontinuously, so consumption and utility decrease discontinuously. Hence, these individuals will set $b^{pub}_l = m_s$.  

\[ \Box \]
